# **Does the choice of fund performance measure matter?**

## **Abstract**

This paper investigates whether investment strategies using rankings based on different portfolio performance measures lead to different future abnormal returns. A set of 13 commonly used risk-adjusted performance measures is applied to a dataset of US equity mutual funds over the period July 1970 to September 2019. The results show some evidence of short-term performance persistence, suggesting that portfolios formed on different performance measures *ex-ante* can generate abnormal returns *ex-post*. A strategy of investing in the top performing funds and shorting the poor performing funds provides positive excess returns and five-factor alphas. However, when adjusting for the momentum factor, there is less evidence of abnormal performance. The results also show that overall there is little difference arising from the use of different performance measures, but with one notable exception: the Rachev ratio.

## **1 Introduction**

Portfolio performance evaluation is an important and much debated subject in the finance literature. Since the advent of modern portfolio theory and the Capital Asset Pricing Model (CAPM) in the 1960s, many portfolio performance measures have been proposed in the literature. Traditionally, it is considered that use of the ubiquitous Sharpe ratio (Sharpe, 1966) as the performance measure of choice requires that returns have a normal distribution, investors have a quadratic utility function or otherwise accept volatility as the measure of risk. More recent research, however, indicates that the Sharpe ratio is the appropriate performance measure under more general conditions, namely that returns follow an elliptically symmetric distribution.

Nonetheless, traditional performance measures do not explicitly take into account the risk premia due to higher moments or co-moments. Research into this issue may be divided into two groups. First, several studies have extended standard portfolio theory to incorporate the effect of skewness (Arditti, 1967; Arditti & Levy, 1975; Kraus & Litzenberger, 1976). Harvey and Siddique (2000) develop an asset pricing model with conditional coskewness where risk averse investors prefer positively skewed assets to negatively skewed assets. Assets that decrease a portfolio's skewness are less desired and thus should have higher expected returns<sup>1</sup>. Additionally, Dittmar (2002) finds a preference for lower kurtosis. Assets that increase a portfolio's kurtosis are less desirable and should also have higher expected returns. A second group of papers considers asymmetry in returns and focuses on risk measures derived from the tails of the distribution. These measures have come to be known as downside risk measures. They are considered theoretically more robust as they do not assume normality of returns and do not rely on volatility as a measure of risk. They are widely used in portfolio performance evaluation. At the present time there is no consensus about which risk measure is the most appropriate to incorporate in performance measures and there is an ongoing debate about whether the choice of such measures matters.

Recent studies have questioned whether the choice of performance measure matters in practice. The empirical evidence is equivocal. Some studies show that the use of different risk-adjusted performance measures does not seem to matter for investment fund decisions based on performance ranked portfolios (Auer, 2015; Eling & Faust, 2010; Eling & Schuhmacher, 2007; Eling, 2008). This is because the empirical correlation between performance measures and the Sharpe ratio is equal to or close to unity. Thus, there is no difference in fund rankings resulting from the use of different performance measures. Others studies document that it does matter for some performance measures under consideration (Zakamouline, 2011; Ornelas, Silva Júnior, &

Fernandes, 2012; Adcock et al., 2017; Grau-Carles, Doncel, & Sainz, 2019). In particular, both Zakamouline (2011) and Ornelas, Silva Júnior, and Fernandes (2012) point out that fund rankings can vary substantially depending on the performance measure used. In addition, as first pointed out by Zakamouline (2011), many performance measures are monotonic functions of the Sharpe ratio when computed using formulae based on the normal distribution. In such cases, the correlation between a performance measure and the Sharpe ratio will be unity or close to it (see for example Adcock et al., 2012). Furthermore, Schuhmacher and Eling (2012), Adcock et al. (2012, 2017) and Guo and Xiao (2016) show that for a broad class of probability distributions of portfolio returns, many performance measures that have been reported in the literature are also monotonic functions of the Sharpe ratio. Such distributions are referred to as location-scale distributions. The class includes distributions that exhibit asymmetry as well as symmetric forms of non-normality. As reported in Zakamouline (2011) and Adcock et al. (2017), monotonicity with respect to the Sharpe ratio can fail if returns follow different location-scale distributions. From a practical perspective, the usefulness of a given performance measure for a set of funds depends on the homogeneity of the distributions of returns<sup>2</sup>.

The implications of the debate summarized above are of significant practical importance. Investors typically pay great attention to fund performance rankings in their investment decisions (Capon, Fitzsimons, & Prince, 1996), implicitly assuming performance persistence. However, if the ranking of funds changes according to the performance measure used, portfolios formed on the basis of these rankings may lead to different future performance. As is well known, the performance of a portfolio is often very different *ex-post* from that expected *ex-ante*. Thus, even if two or more performance measures are highly correlated when a set of funds is ranked, there is no guarantee that the *ex-ante* rankings will correspond to realized performance. In short, does the

similarity of ranking *ex-ante* lead to similarity of performance *ex-post*? If there are differences, an investor would prefer to carry out the *ex-ante* ranking using a performance measure which led to superior performance *ex-post*. This is an important issue that requires further research. Furthermore, and to the best of our knowledge, this is the first study exploring the persistence of mutual fund performance using a set of performance measures that are commonly used by practitioners or reported in the literature or both.

The purpose of this paper is to investigate whether there is any performance measure that is better able to detect performance persistence and whether different performance measures used *ex-ante* result in different portfolio performance *ex-post*. Although there is extensive empirical evidence addressing the correlations between different performance measures (for example Eling & Schuhmacher, 2007), these analyses are static in approach. They ignore the possibility of time-varying correlations and other changes in distribution and the consequences for *ex-post* performance of ranking funds *ex-ante*. If correlations between the different performance measures do vary over time, for example, the use of alternative measures may impact *ex-post* performance. By simulating investment strategies over time and computing excess returns over benchmark, our analysis captures the dynamic effect of changing correlations and of changing distributions of returns.

In this paper, we report the results of a study based on the Sharpe ratio and twelve other performance measures. According to Cogneau and Hübner (2009a,b) over one hundred performance measures have been reported in the literature. The ones selected for inclusion in this paper are a combination of measures that are well-known to practitioners and some that are widely considered in the literature. As the results in Section 4 show, most of these measures lead to similar performance characteristics *ex-post*. Inclusion of measures that are less well-known to

practitioners serves to remind that use of new or ostensibly different performance measures should be done with care and after investigation. A second reason for covering a number of measures is that most of the previous studies that investigate whether past performance is related to future performance use a single or a very limited set of performance measures to rank funds. For example, Hendricks, Patel, and Zeckhauser (1993), Brown and Goetzmann (1995), Elton, Gruber, and Blake (1996, 2012), Carhart (1997) and Bollen and Busse (2005) document evidence of performance persistence when ranking funds on the basis of raw returns and abnormal returns (alphas). Some of these authors find that performance persistence is short-lived (see for example Hendricks, Patel, & Zeckhauser, 1993; Bollen & Busse, 2005) while others observe performance persistence over periods longer than one year (Elton, Gruber, & Blake, 1996, 2012). Furthermore, Carhart (1997) attributes the persistence phenomenon to the momentum effect and observes that persistence is concentrated in the poor performing funds.

The dataset used in this paper consists of portfolios of US domestic equity funds over the period July 1970 to September 2019. Each month portfolios of funds are created based on rankings of funds that result from applying the different risk-adjusted performance measures. The *ex-post* performance of these portfolios of funds is measured using excess returns, Carhart (1997) four-factor alphas and Fama and French (2015) five-factor alphas.

The paper is structured as follows. In section two the risk-adjusted performance measures are briefly presented and the methodology used to assess *ex-post* fund performance is described. Section three presents the data. Section four reports and discusses the empirical results. Section five concludes. Additional detailed supporting results, such as descriptive statistics, are available from the corresponding author.

## 2 Methods

### 2.1 Risk-adjusted performance measures used in ranking funds

We apply a set of risk-adjusted performance measures to analyze if investment strategies using rankings based on these measures lead to different *ex-post* performance results. Each period fund performance is assessed using different risk-adjusted measures. The use of some of these performance measures is strongly motivated by the finance literature and others are commonly used in practice by fund managers. The best known risk-adjusted performance measure and probably the most used in practice is the traditional Sharpe ratio (Sharpe, 1966). In the context of modern portfolio theory, there are also strong theoretical arguments for the use of the Appraisal ratio as a measure of performance (Treynor & Black, 1973). More recently, Goetzmann, Ingersoll, Spiegel, and Welch (2007) develop an alternative to the traditional Sharpe ratio that they call as the Manipulation Proof Performance Measure. As this measure captures the whole profile of the returns distribution, Goetzmann et al. (2007) claim that it is immune to fund manager manipulation that may occur when performance measures based only on the first two moments are used. General difficulties associated with the use of the traditional performance measures in the context of non-elliptically symmetric distributed returns also motivated the development of an alternative downside risk measurement framework. In addition, the early 1990's witnessed an intensification of the ongoing debate about good risk management practices. As a consequence, several alternative downside risk-adjusted performance ratios were proposed. These ratios are mainly based on the Lower Partial Moments (like the Modified Sortino and Farinelli-Tibiletti ratios) and on the Value at Risk (Excess Return on Value at Risk, Excess Return on Conditional Value at Risk and Rachev ratio). Over the years a set of performance measures based on drawdown (Calmar ratio, Sterling ratio and Burke ratio) became very popular among practitioners and therefore they are also often

included in studies that aim the comparison of different measures of performance. The list of measures and accompanying descriptions are presented in an appendix. We use the nomenclature as in Zakamouline (2011) and Adcock et al. (2012).

Overall, 13 performance measures are computed and analyzed in detail. These measures are part of a larger set of 82 performance measures that were computed, and whose results are available upon request<sup>3</sup>.

## **2.2 Constructing and evaluating portfolios**

We analyze equally weighted and value weighted portfolios of mutual funds ranked according to different risk-adjusted performance measures, as described in the previous section. Every month we create portfolios based on deciles of funds ranked according to their past performance – the rank portfolios. An estimation window of 60 months (5 years) is used to compute estimates of performance. In each period the oldest observation is dropped and the most recent observation is added. For each rank portfolio we end up with a time series of monthly portfolio returns (over the period July 1970 to September 2019).

The *ex-post* performance of these rank portfolios is evaluated by computing excess returns, the four-factor alpha (Carhart, 1997) and the five-factor alpha (Fama & French, 2015). The motivation for using different performance measures in the ranking procedure and in the *ex-post* performance assessment follows from Carhart's (1997) argument that using different measures to sort funds and estimate *ex-post* performance avoids possible model biases. In addition, by controlling for additional sources of systematic risk, the four- and five-factor model alphas capture solely the returns associated with fund managers' skills. It is worth noticing that the reward-to-risk ratios used *ex-ante* do not control for multiple sources of risk and can seemingly generate the appearance

of abnormal performance that is simply due to the returns associated with the omitted factor loadings. Considering the Carhart (1997) four factor model, the performance measure (alpha) is obtained from the following equation

$$r_{p,t} - r_{f,t} = \alpha_p + \beta_p(r_{m,t} - r_{f,t}) + s_pSMB_t + h_pHML_t + p_pMOM_t + \epsilon_{p,t}, \quad (1)$$

where  $r_{p,t}$  represents fund returns,  $r_{f,t}$  is the risk free rate,  $\alpha_p$  represents the fund performance measure,  $r_{m,t}$  represents market returns,  $SMB_t$ ,  $HML_t$  and  $MOM_t$  represent the size, value and momentum factors respectively.  $SMB_t$  is the return on a diversified portfolio of small stocks minus the return on a portfolio of big stocks,  $HML_t$  is the return difference between portfolios of value stocks and growth stocks, and  $MOM_t$  is the return difference between high prior return portfolios and low prior return portfolios.

The performance measure based on the Fama and French (2015) five factor model results from

$$r_{p,t} - r_{f,t} = \alpha_p + \beta_p(r_{m,t} - r_{f,t}) + s_pSMB_t + h_pHML_t + r_pRMW_t + c_pCMA_t + \epsilon_{p,t}, \quad (2)$$

where  $RMW$  is the profitability factor, measured as the difference between the returns on diversified portfolios of stocks with robust and weak profitability and  $CMA$  is the investment factor, measured as the difference between the returns on diversified portfolios of stocks of low and high investment firms. The other variables are as defined above.

We also compute two types of differences portfolios. The first one corresponds to the difference in returns between the highest performance decile and the lowest performance decile considering the same risk-adjusted performance measure. This differences portfolio simulates the performance that results from a strategy of buying the top decile and shorting the bottom decile portfolio (long-short strategy), thereby assessing the profitability of exploring a performance persistence

investment strategy. The second one corresponds to the difference in returns between the different performance measures of the same decile portfolio. The aim is to assess if the choice of a specific performance measure, particularly at each of the extreme deciles (deciles 1 and 10), leads to different *ex-post* performance.

### 3 Data

The dataset consists of US domestic equity funds of different categories obtained from the CRSP database. Returns with a monthly frequency are available from December 1961 onwards. Only funds with an objective code of EQC (Equity, Domestic and Cap-based) and EQY (Equity, Domestic and Style) are considered. All funds classified as ETFs, ETNs and Index funds are excluded. Funds with less than 60 months of observations are also eliminated. In the case of funds with multiple share classes, only one is considered: the one with the longest historic record and, if necessary, the one with the largest Total Net Assets (TNA). To avoid the incubation bias (Evans, 2010)<sup>4</sup> and the omission bias (Elton, Gruber, & Blake, 2001)<sup>5</sup> the first three years of data and funds with less than \$15 million in TNA, respectively, are removed. This leads to a final dataset of **3966** funds. Figure 1 reports the number of funds with 60 months of history over the period December 1969 to September 2019. As can be observed, there is a considerable increase in the number of funds throughout this period.

[Insert figure 1 here]

The first decile portfolios are formed in June 1970. Funds that disappear during a particular month are included in the portfolios until they disappear and then the portfolios weights are readjusted

accordingly. The *ex-post* performance of these decile portfolios is then assessed considering the period July 1970 to September 2019 (a total of 591 monthly return observations). Fund returns are net of management expenses and security-level transaction costs, but do not include load fees. The monthly risk free rate as well as the monthly returns of the risk factors (market, size, value, momentum, profitability and investment factors) over the same period were downloaded from the Professor Kenneth French webpage.

## **4 Empirical results and discussion**

### **4.1 Performance persistence with monthly portfolio rebalancing**

In this section we analyze whether there is any performance measure that is better able to detect performance persistence. The results consider a total of 13 different risk-adjusted performance measures, as listed in appendix. The ERVaR and ERCVaR are computed both parametrically assuming a Normal-GARCH model<sup>6</sup> and non-parametrically by using historical simulation; that is, using the empirical distribution of past returns.

We start by analyzing equally weighted decile portfolios formed on the basis of the different risk-adjusted performance measures. In each month, funds are ranked according to their performance over the previous 60 months and decile portfolios of funds are formed. These portfolios are then rebalanced monthly. Decile 1 corresponds to the portfolio of the bottom performing funds and decile 10 corresponds to the portfolio of the top performing funds. Value weighted decile portfolios are also analyzed. *Ex-post* portfolio performance is assessed using excess returns over the market benchmark, as well as alphas based on the Carhart (1997) and Fama and French (2015) models.

Table 1 reports the mean excess returns over the market benchmark<sup>7</sup> for the equally weighted decile portfolios over the period from July 1970 to September 2019<sup>8</sup>. The results show that, in general, the excess returns are negative and statistically significant at the 5% level in the bottom performing deciles (deciles 1 to 5). In decile 1, with the exception of the portfolios formed using the RR, all the other portfolios present negative and statistically significant at the 5% level ranging from -0.247% (for the portfolio formed using Sharpe ratio) to -0.087% (for the portfolio formed using RR). Deciles 8 to 10 tend to present positive excess returns, although none is statistically significant. For most risk-adjusted performance measures there is a tendency for the highest performance deciles to present the highest excess returns. The exception is observed mainly in relation to the RR, for which there is no clear tendency of higher or lower excess returns across different deciles. In each decile, excess returns are similar for the majority of the performance measures, with the exception of the RR<sup>9</sup>.

[Insert Table 1 here]

To further explore these results, we also analyze the *ex-ante* correlations over time between the Sharpe ratio and the other performance measures. For each year (in June), we test the null hypothesis that the correlation between the Sharpe ratio and other performance measures is equal to one (Adcock et al., 2012) and also analyze the correlation between the rankings produced by these performance measures. Unreported results suggest that some performance measures are more stable than others as far as the correlation with the Sharpe ratio is concerned. The null hypothesis of unit correlation is rejected in all the years for the RR. With regards to the other measures, the rejection of the null occurs occasionally. For the ranking correlations, the unreported results show changes in rank ordering, which is consistent with the findings reported by Zakamouline (2011) and Ornelas et al. (2012). It is worth mentioning that the RR also presents the lowest rank

correlation with the Sharpe ratio. Differences when funds are ordered using the RR when compared to the other performance measures means there is a failure of monotonicity with respect to the Sharpe ratio. As reported in Table 1 there is a noticeable difference in the *ex-post* performance of portfolios when the constituent funds are ranked using RR. A detailed analytical study of this phenomenon is beyond the scope of this paper, but results reported in Adcock et al. (2017) provide a demonstration that monotonicity is more likely to fail for the RR than for at least some of the other performance measures. That paper also demonstrates that monotonicity failure is less likely for ERVaR and ERCVaR. The other 8 performance measures reported in Table 1 are not amenable to study by closed form analytical methods. However, the similarity of fund performance across all deciles arising from their use suggests nonetheless that monotonicity of the other performance measures with respect to the Sharpe ratio, and hence high correlation and similar fund rankings, is preserved, although to some extent this is not the case for the MPPM<sup>10</sup>. The variability in the *ex-ante* correlations implies that fund selection will vary depending on the performance measure used. Overall, however, the *ex-post* performance is not that different for most of the performance measures.

Tables 2 and 3 present the *ex-post* performance of the equally weighted decile portfolios estimated by the Carhart (1997) four factor and the Fama and French (2015) five factor models, respectively. The results on the four factor model (Table 2) show that decile 1 (the lowest performance portfolio) alphas are mostly negative and statistically significant (at the 5% level), ranging from -0.196% and -0.083%. We also observe a tendency for alphas to increase from the bottom performing decile to the top performing decile, with the exception of the RR, for which there is no clear tendency and even a slightly more negative alpha for the top performing decile (-0.112%) than for the bottom performing decile (-0.083%) is observed. The fact that the decile portfolios' performance increase

almost monotonically is consistent with the existence of persistence of alphas. All alphas of decile 10 are neutral, and excluding the one obtained using the RR, they vary between -0.021% and 0.052%. With respect to the five-factor alphas (Table 3) the results are similar. Decile 1 alphas are all negative and statistically significant, ranging from -0.258% and -0.108%. In turn, decile 10 alphas are all positive, although only two are statistically significant (ModSortino and MPPM), ranging from 0.035% and 0.123%. It is worth pointing out that the evidence of underperformance in decile 1 is stronger than that observed with the four factor model as, with the exception of the RR, all negative alphas are statistically significant at the 1% level. Interestingly, the monotonicity of the alphas with respect to the deciles is stronger numerically for the four factor model than the five factor model.

[Insert Table 2 here]

[Insert Table 3 here]

Unreported results on the *ex-post* performance of value weighted portfolios are similar in terms of excess returns. In relation to *ex-post* alphas, those of the bottom portfolios are less negative, suggesting that the negative performance of the bottom decile portfolios may be driven by smaller size funds<sup>11</sup>.

Table 4 presents excess returns, four-factor alphas, and five-factor alphas of a portfolio that corresponds to the differences between the top (10) and bottom (1) equally weighted and value weighted deciles. This portfolio shows the returns that result from a strategy of buying the top decile funds and shorting the bottom decile funds. As can be observed, we find positive and statistically significant (at the 5% level) excess returns and alphas in most of the differences portfolios formed on the basis of different measures of performance. In the case of the differences

portfolios formed on the RR and, to less extent, the MPPM there is far less evidence of statistically significant alphas. These results seem to suggest that the RR and the MPPM do the worst job in predicting future performance. Furthermore, the evidence in favor of an outperformance of an investment strategy exploiting performance persistence is stronger when we use returns and the five-factor alphas to assess *ex-post* performance, with most values exhibiting statistical significance even at the 1% level. However, the evidence of abnormal returns is scarce when the four factor model is used for value weighted portfolios. In fact, in the case of value weighted portfolios we find evidence of performance persistence (at the 5% level) only for four of the measures (Sharpe, ERVaR-NG, ERCVaR-HS and AR-CAPM). The weaker evidence of a profitable strategy exploiting performance persistence observed in the context of the Carhart (1997) four factor model suggests that abnormal returns are somewhat driven by short-term momentum and raises the issue of whether the five factor model of Fama and French (2015) does a good job in evaluating performance<sup>12</sup>. Analyzing in more detail the regressions estimates we observe that the explanatory power of both models, measured by the R-squareds, is similar and always above 90%. In the case of the four factor model, the size and momentum are relevant risk factors. The size factor is statistically significant across the different deciles and the different performance measures. The momentum factor is positive and statistically significant for the top performing deciles, whereas it is negative in some of the bottom performing deciles. In relation to the five factor model the most relevant factors are size and profitability.

[Insert Table 4 here]

## 4.2 Implications of using different performance measures

Besides analyzing the *ex-post* performance of an investment strategy that consists in selecting funds according to a specific performance measure, it is also relevant to investigate whether using different measures of performance to rank funds matters. In this section, we focus on the latter issue by assessing whether there are differences in the performance of decile portfolios formed on the basis of rankings of different risk-adjusted performance measures. For each pair of performance measures, a portfolio that corresponds to the return differences is formed. Then, the *ex-post* performance of the differences portfolio for each pair of measures is computed using, as before, excess returns, four-factor alphas and five-factor alphas. Tables 5 to 8 report estimates of performance differences of equally weighted portfolios (performance differences between portfolios formed using measure in column minus measure in line). In the sake of brevity, we only report the results for the extreme decile portfolios (decile 1 represents the bottom performing funds and decile 10 represents the top performing funds) and based on excess returns and four-factor alphas<sup>13</sup>. The entries in these tables are derived from the corresponding cells in tables 1 and 2.

Tables 5 and 6 report the results based on excess returns for deciles 1 and 10, respectively. For the majority of the pairs of performance measures we do not observe statistically significant differences (at the 5% level) in *ex-post* excess returns. Only the use of the RR seems to lead to significant return differences. For decile 1, the RR tends to yield higher returns while for decile 10 it seems to generate lower returns. This seems to indicate that this measure is not able to correctly identify the best and the worst performing funds.

[Insert Table 5 here]

[Insert Table 6 here]

Tables 7 and 8 show the *ex-post* performance differences (measured by four-factor alphas) for each pair of performance measures for deciles 1 and 10, respectively. In the case of decile 1, the results are similar to those obtained with excess returns (Table 5). Once again, only the use of the RR generates statistically significant performance differentials. For decile 10, the systematic use of the RR, in comparison with the other *ex-ante* performance measures, leads to worse *ex-post* performance as observed previously when measuring performance with excess returns. Additionally, the use of the MPPM also leads to worse *ex-post* performance compared to some other performance measures.

[Insert Table 7 here]

[Insert Table 8 here]

Although not reported, we also analyze the *ex-post* performance differences for each pair of performance measures for value weighted portfolios. In general, the results are similar in what concerns the fact that most of the alphas for the differences portfolios are not different from zero. The majority of the performance measures under analysis seem to lead to similar future performance results. When statistically significant differences do occur, in general they are related with the use of the RR, the MPPM, the Calmar, the Sterling and the Burke ratios. However, the impact of using these performance measures is not clear, as the reported differences vary between positive and negative.

#### **4.3 Portfolio turnover and the impact of transaction costs**

An important issue when analyzing the long-short investment strategy described above (buying top performers and shorting bottom performers) is the frequency of trading and the impact of transaction costs. In this section we investigate whether the evidence of short term persistence can

be exploited in practice by investors. For this purpose, portfolio turnover is computed and the impact of transaction costs on portfolio performance is analyzed. As our analysis focuses on portfolios of mutual funds we need to take into account possible load fees they might charge. Load fees differ across funds. Some funds have front end fees and/or back end fees. Usually, front end fees are waived and back end fees vary according to the investment horizon. Considering the typical load fees structure of US equity funds, we analyze the impact of transaction costs of 0.25% and 2%<sup>14</sup>.

Table 9 reports the turnover of the equally weighted portfolios. Monthly turnover ranges from around 8% to 15%. In general, the levels of portfolio turnover are lower in the extreme deciles (with decile 10 exhibiting the lowest figures) and higher for the middle ones. Anyhow, in any decile, the turnover does not vary much on the *ex-ante* performance measure chosen. Even the RR leads to similar values of this indicator. A similar pattern is observed for value weighted portfolios, although in this case the levels of turnover are higher, ranging between 12% and 35%, with all decile portfolios formed using RR presenting the lowest values.

[Insert Table 9 here]

Table 10 shows the differences in performance for equally weighted portfolios that arise from this long-short strategy considering transaction costs of 0.25% and 2%<sup>15</sup>. As expected, *ex-post* performance decreases as transactions costs increase. For low values of transactions costs of 0.25%, the results show that investors can profit from exploiting persistence strategies. However, the evidence of abnormal returns is weaker when the momentum factor is accounted for. With transactions costs of 2%, long-short strategies based on any of the *ex-ante* performance measures lead to unprofitable results whatever *ex-post* performance measure is considered. For value

weighted portfolios, even for 0.25% transaction costs, there is no evidence of performance persistence when *ex-post* performance is measured by four-factor alphas.

[Insert Table 10 here]

#### **4.4 Alternative portfolio cut-offs and rebalancing periods**

For robustness purposes we also form portfolios with different cut-offs: considering the top 30%, the middle 40% and the bottom 30% performing funds. The results in Table 11 show that the differences between top performing and bottom performing funds are lower compared with those obtained with the decile portfolios, as expected. Compared with the results of Table 4, there is slight less evidence of performance persistence for equally weighted portfolios. It is worth mentioning that two of the *ex-ante* measures (Sharpe and ERCVaR-NG) seem to lead to persistent abnormal returns whatever *ex-post* performance measure is used. This result is robust for alternative portfolio cut-offs.

[Insert Table 11 here]

So far, the results considered monthly rebalancing of the portfolios. We also analyze the results obtained with an annual rebalancing strategy. Each year (end of June), funds are ranked according to their performance over the previous 60 months and decile portfolios of funds are formed. The composition of the portfolios is then maintained until June of the following year. The *ex-post* performance results (excess returns, four-factor and five-factor alphas) of the differences portfolios between the top (decile 10) and bottom (decile 1) performing funds, considering annual rebalancing, are reported in Table 12.

[Insert Table 12 here]

Comparing the results in Table 12 with those reported in Table 4, we observe less evidence of abnormal returns from investment strategies exploiting performance persistence, particularly when performance is measured with excess returns and five-factor alphas. In fact, abnormal returns (at the 5% level) hold mainly for the equally weighted portfolios and when performance is measured with the four-factor alpha. For value weighted portfolios a few measures seem to exhibit predictive ability of future performance: Sharpe, ERVaR-NG, ERVaR-HS, FT(1,2) and AR-CAPM ratios. These findings suggest that performance persistence is more concentrated in smaller size funds. The fact that the five-factor alphas are no longer statistically significant confirms that the evidence in favor of performance persistence for monthly rebalancing with this model is mostly due to the short-term momentum effect.

With regards to the question of whether using different risk-adjusted performance measures to rank funds is relevant, the unreported results for the extreme portfolios (deciles 1 and 10) are similar to those obtained with monthly rebalancing, as in most cases there are no statistically significant differences in performance for any pairs of performance measures. The few cases in which such differences exist are associated with the use of RR, AR-CAPM and FT(1,1).

## **5 Conclusions**

In this paper, we investigate the extent to which the *ex-ante* use of a set of 13 commonly used performance measures generates abnormal *ex-post* performance and whether the performance measure used makes any difference. The study is based on a dataset of monthly returns of US equity mutual funds from 1970 to 2019. The paper presents a detailed analysis of the effect of different performance measures on *ex-post* performance. In general, the results show that the use of alternative performance measures leads to very similar *ex-post* performance. The main

exception is the Rachev ratio, which is unable to discriminate between the performance of funds in the dataset used in this study. The main results of the study are as follows.

For each risk-adjusted performance measure, we analyze the *ex-post* performance of a strategy of holding decile portfolios formed using fund rankings on the measure. We also investigate a long-short strategy of buying the top decile and selling the bottom decile funds, thus simulating an investment strategy exploiting persistence in fund performance. The estimates of the performance measures and hence the constituents of the decile portfolios are recomputed each month. The results show that decile portfolio performance increases almost monotonically from the worst decile to the best. This indicates that selecting the best funds according to the *ex-ante* values of a performance measure leads to higher performance *ex-post*. That is, there is signal in the time series of fund returns and in the derived time series of performance measures. The results of the long-short investment strategy show that investors who exploit a persistence strategy can obtain abnormal returns. However, when adjusting for the momentum risk factor, there is less evidence of outperformance. These results suggest that short term performance persistence is partly driven by momentum. When trading costs are deducted, abnormal performance is observed only at the lowest level of transaction costs, 0.25% round trip. In the case of value weighted portfolios, the evidence of outperformance measured by four-factor alphas does not survive even low transaction costs. These results are robust to alternative portfolio cut-offs. Furthermore, the evidence of outperformance measured by excess returns and five-factor alphas almost disappears with an annual rebalancing investment strategy, suggesting that the evidence in favor of performance persistence for monthly rebalancing is mostly due to the short-term momentum effect.

To summarize; the results of this study suggest that there is no reason to use any performance measure other than the Sharpe ratio, even though *ex-ante* there can be considerable differences in

fund rankings. To the best of our knowledge this is the first study of the *ex-post* effect of different performance measures. It complements other papers in the literature that report high correlation, often values of unity or close to it, of performance measures with the Sharpe ratio. An interesting albeit minor finding is that there is evidence to support the use of GARCH models for the computations of estimates of volatility. To conclude, it is important to note that as this is an empirical study based on data from the US market, different results could arise for datasets of asset or fund returns from other markets. It is well known that high or even unit correlations with the Sharpe ratio arise as a result of theoretical properties of the return distributions. These properties may be satisfied by US mutual funds collectively, but would not necessarily be met by other datasets.

This Table reports mean excess returns over the market benchmark and the corresponding p-values of the paired t-test of the mean being equal to zero for equally weighted decile portfolios of funds ranked according to the different risk-adjusted performance measures. The t-test is performed with heteroscedasticity and autocorrelation consistent standard errors following Newey and West (1987, 1994). The market benchmark is US market return available on the Professor Kenneth French webpage. Portfolios are rebalanced monthly. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. Decile 1 corresponds to the bottom performing funds and decile 10 to the top performing funds. Both mean excess returns and p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

This Table reports the Carhart (1997) four-factor alphas and the corresponding p-values of the t-test of alpha being equal to zero for equally weighted decile portfolios of funds ranked according to the different risk-adjusted performance measures. The reported p-values are based on standard errors corrected for the presence of autocorrelation and heteroscedasticity using the procedure suggested by Newey and West (1987, 1994). Portfolios are rebalanced monthly. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. Decile 1 corresponds to the bottom performing funds and decile 10 to the top performing funds. Both alphas and p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

This Table reports the *ex-post* performance of the differences portfolios between the top performing funds (D10) and the bottom performing funds (D1) considering the different risk-adjusted performance measures. Portfolios are rebalanced monthly. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. *Ex-post* performance is measured by excess returns, Fama and French (2015) five-factor alphas and Carhart (1997) four-factor alphas. Excess returns, alphas and their corresponding p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

This Table reports the mean excess returns and the corresponding p-values of the paired t-test of the mean being equal to zero for the differences portfolios between each pair of performance measures (measure in column minus measure in line) considering the bottom performing funds (equally weighted decile 1). The t-test is performed with heteroscedasticity and autocorrelation consistent standard errors following Newey and West (1987, 1994). Portfolios are rebalanced monthly. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. Both alphas and p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

This Table reports the mean excess returns and the corresponding p-values of the paired t-test of the mean being equal to zero for the differences portfolios between each pair of performance measures (measure in column minus measure in line) considering the top performing funds (equally weighted decile 10). The t-test is performed with heteroscedasticity and autocorrelation consistent standard errors following Newey and West (1987, 1994). Portfolios are rebalanced monthly. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. Both alphas and p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

Table 7 – Carhart (1997) four-factor alphas of the differences portfolios between pairs of performance measures for bottom performing funds (D1)

This Table reports the Carhart (1997) four-factor alphas and the corresponding p-values of the t-test of the alpha being equal to zero for the differences portfolios between each pair of performance measures (measure in column minus measure in line) considering the bottom performing funds (equally weighted decile 1). The reported p-values are based on standard errors corrected for the presence of autocorrelation and heteroscedasticity using the procedure suggested by Newey and West (1987, 1994). Portfolios are rebalanced monthly. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. Both alphas and p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

This Table reports the *ex-post* performance of the differences portfolios between the top performing funds (D10) and the bottom performing funds (D1) considering the different risk-adjusted performance measures. Portfolios are rebalanced monthly. Results with transaction costs of 0.25% and 2% are reported. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. *Ex-post* performance is measured by excess returns, Fama and French (2015) five-factor alphas and Carhart (1997) four-factor alphas. Excess returns, alphas and their corresponding p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

Table 11 – Differences in *ex-post* performance between the top (T3) and the bottom (T1) performing funds: monthly rebalancing

This Table reports the *ex-post* performance of the differences portfolios between the top performing funds (T3, representing the top 30% performing funds) and the bottom performing funds (T1, representing the bottom 30% performing funds) considering the different risk-adjusted performance measures. Portfolios are rebalanced monthly. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. *Ex-post* performance is measured by excess returns, Fama and French (2015) five-factor  $\alpha$  and Carhart (1997) four-factor alphas. Excess returns, alphas and their corresponding p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

Table 12 – Differences in *ex-post* performance between the top (D10) and the bottom (D1) performing funds: annually rebalancing

	Equally weighted portfolios						Value weighted portfolios					
	D10-D1 Mean excess returns		D10-D1 Fama and French (2015) five-factor alphas		D10-D1 Carhart (1997) four-factor alphas		D10-D1 Mean excess returns		D10-D1 Fama and French (2015) five-factor alphas		D10-D1 Carhart (1997) four-factor alphas

This Table reports the *ex-post* performance of the differences portfolios between the highest performing funds (D10) and the bottom performing funds (D1) considering the different risk-adjusted performance measures. Portfolios are rebalanced annually. ERVaR-HS and ERCVaR-HS are computed on the basis of a VaR and CRVaR using historical returns and numerical integration; and ERVaR-NG is computed based on parametric VaR using a normal-GARCH model. *Ex-post* performance is measured by excess returns, Fama and French (2015) five-factor alphas and Carhart (1997) four-factor alphas. Excess returns, alphas and their corresponding p-values are expressed in percentage. Values reported in bold are statistically significant at the 5% level.

## Appendix – *Ex-ante* risk-adjusted performance measures

Performance measure	Reference	Formula
Sharpe ratio	Sharpe (1966)	$SR = \frac{(\mu - r_f)}{\sigma}$
Appraisal ratio	Treynor and Black (1973)	$AR = \frac{\alpha}{\sigma_\epsilon}$
Manipulation Proof Performance Measure	Goetzmann et al. (2007)	$MPPM = \{\Delta t(1 - \omega)\}^{-1} \log \left\{ T^{-1} \sum_{t=1}^T e^{(1-\omega)R_t} \right\}$
Expected excess return to Value at Risk	Dowd (2000)	$ERVaR = \frac{(\mu - r_f)}{VaR_\alpha}$
Expected excess return to Conditional Value at Risk	Martin, Rachev, and Siboulet (2003)	$ERCVaR = \frac{(\mu - r_f)}{CVaR_\alpha}$
Rachev ratio	Rachev, Jašić, Stoyanov, and Fabozzi (2007)	$RR(\alpha, \beta) = \frac{CVaR_\beta(r_f - x)}{CVaR_\alpha(x - r_f)}$
Farinelli-Tibiletti ratio	Farinelli and Tibiletti (2008)	$FT(\alpha, \beta) = \frac{\{H_\alpha(r_f)\}^{\frac{1}{\alpha}}}{\{L_\beta(r_f)\}^{\frac{1}{\beta}}}; \alpha, \beta \geq 1$
Modified Sortino ratio	Pedersen and Satchell (2002)	$SP = \frac{(\mu - r_f)}{\sqrt{L_2(r_f)}}$
Calmar ratio	Young (1991)	$Calmar = \frac{\mu - r_f}{-MD_1}$
Sterling ratio	Kestner (1996)	$Sterling = \frac{\mu - r_f}{\frac{1}{N} \sum_{i=1}^N MD_i}$
Burke ratio	Burke (1994)	$Burke = \frac{\mu - r_f}{\sqrt{\sum_{i=1}^N MD_i^2}}$

Notes:

$\mu$  represents the portfolio average returns;

$r_f$  is the risk free rate;

$\sigma$  represents the standard deviation of the returns;

$\alpha$  measures the abnormal return using the CAPM;

$\sigma_\epsilon$  measures the unsystematic risk proxied by the standard deviation of the model residuals;

$\{R_t\}$  represents a time series of fund returns;

$\omega$ , a scalar, denotes risk aversion. Following both Goetzmann et al. (2007) and Brown, Kang, In, and Lee (2010), a risk aversion coefficient of 3 is used as it is considered to be representative of institutional investors;

$\Delta t$  is the length of the time interval;

$VaR_\alpha$  is the value-at-risk, generally defined as the maximum expected loss over a given horizon period at a given probability of  $1 - \alpha$ ;

$CVaR_\alpha$  is the expected loss under the condition that VaR is exceeded;

$CVaR_\beta(r_f - x)$  is the conditional expected excess return in the right hand tail of the distribution and  $CVaR_\alpha(x - r_f)$  is the conditional expected excess return in the left hand tail of the distribution. Following Zakamouline (2011), a combination of  $\alpha = 0.05$  and  $\beta = 0.05$  is used to compute the Rachev ratio;

$H_\alpha$  and  $L_\beta$  are, respectively, the upper and lower partial moments of any order  $\alpha$  and  $\beta$ . Both lower and upper partial moments are defined with respect to a reference point  $\tau$  which may take any real value:  $L_\omega(\tau) = \int_{-\infty}^{\tau} (\tau - x)^\omega f(x) dx$  and  $H_\omega(\tau) = \int_{\tau}^{\infty} (x - \tau)^\omega f(x) dx$ , where  $f(\cdot)$  denotes the probability density function of portfolio returns. It is usually assumed that  $\omega \geq 1$ . In practice usually  $\omega = k$  is an integer, typically equal to 1 or 2;

$MD_1$  represents the lowest return in a given time series of returns and  $N$  represents some predefined set of the largest drawdowns. Similarly to Eling and Schuhmacher (2007),  $N$  is set equal to 5 for the computation of both the Sterling and the Burke ratios.

---

<sup>1</sup> Ding and Shawky (2007), Kostakis (2009) and Moreno and Rodríguez (2009) are examples of studies that consider the Harvey and Siddique (2000) model to evaluate fund performance.

<sup>2</sup> In a different approach, Farinelli, Ferreira, Rosselo, Thoeny and Tibiletti (2008) develop an optimal asset allocations framework based on different performance ratios. Overall, they conclude that management decisions should not be based on a single performance ratio. Their study also shows the low forecast ability of the Sharpe ratio in contrast to ratios based on downside-risk measures such as Sortino-Satchell, Generalized Rachev and Farinelli-Tibiletti ratios.

<sup>3</sup> The additional measures consider probabilities of 0.1%, 0.5%, 1% and 2.5%, all combinations of orders 1 to 5 for the *FT* ratios, three additional *AR*, based on the three-factor model of Fama and French (1993), the four-factor model of Carhart (1997) and the five factor model of Fama and French (2015) and the MPPM with risk aversion coefficients of 2 and 4.

<sup>4</sup> Evans (2010) shows that there is an incubation bias in the CRSP mutual fund database. When funds are included in the database for the first time, they bring all their past history (even if they were being privately traded). Since only the most successful incubator funds will be publicly traded, this creates a bias for the incubation period. Evans (2010) shows that an age filter effectively removes this bias.

<sup>5</sup> The omission bias arises due to the different frequencies of returns available on the CRSP database (e.g. monthly or annual returns). To avoid this problem Elton, Gruber, and Blake (2001) restrict the sample of funds to contain only those funds that have over \$15 million in TNA at the beginning of any observation period as CRSP reports monthly data for most funds with over \$15 million in TNA.

<sup>6</sup> When VAR and CVaR are computed parametrically, assuming a Normal-GARCH model, ERVaR and ERCVaR produce exactly the same rankings and therefore only the results for ERVaR (ERVaR-NG) are reported.

<sup>7</sup> As the market benchmark we considered the US market return available on the Professor Kenneth French webpage.

<sup>8</sup> We also analyzed other descriptive statistics for the decile portfolios excess return series. All the decile portfolios exhibit negative skewness and positive excess kurtosis. In all cases we reject the hypothesis of a normal distribution according to the Jarque-Bera test.

<sup>9</sup> The unreported statistics of the excess returns over the risk free rate also show increasing excess returns from decile 1 to decile 10, which are positive and statistically significant in the top performing portfolios and positive but not statistically significant in the bottom performing portfolios.

<sup>10</sup> The low correlation between these measures has also been documented in Eling, Farinelli, Rosselo, and Tibiletti (2011).

<sup>11</sup> To further investigate the relationship between portfolio performance and the ranking of the funds, we run regressions of *ex-post* portfolio performance on the different deciles as follows  $P_{p,d} = a + \beta d + \epsilon_{p,d}$ , where  $P_{p,d}$  is the *ex-post* performance from *ex-ante* performance measure  $p$  in decile  $d$ . We have also allowed the intercept of the regression ( $a$ ) to vary according to *ex-ante* performance measures. The results show that there is a positive and statistically significant relation between *ex-post* performance, measured either by excess returns or four-factor and five-factor alphas, and the deciles. As expected, when we exclude the portfolios based on the RR from this analysis both the slopes of the regressions and the adjusted R-squareds increase.

<sup>12</sup> See for example Barillas and Shanken (2018) for a comparison on alternative asset pricing models. They show that the Fama and French (2015) five factor model is dominated by models that include a momentum factor.

<sup>13</sup> The results across the other deciles are similar.

<sup>14</sup> For each portfolio, transaction costs ( $c$ ) at time  $t$  are equal to  $c_t = c \sum_{i=1}^N |w_{i,t} - w_{i,t-}|$ , where  $\sum_{i=1}^N |w_{i,t} - w_{i,t-}|$  is the portfolio turnover, computed as follows: on month  $t - 1$  the  $i$ th fund has a given weight in the portfolio denoted by  $w_{i,t-1}$ , with  $i = 1, \dots, N$ . The portfolio return is  $r_{p,t} = \sum_{i=1}^N w_{i,t-1} r_{i,t}$ , where  $r_{i,t}$  is the return on the  $i$ th fund on month  $t$ . At moment  $t^-$ , just prior to rebalancing, the actual weight of the  $i$ th fund in the portfolio is  $w_{i,t-} = w_{i,t-1} \frac{1+r_{i,t}}{1+r_{p,t}}$ . The required rebalancing at time  $t$  is equal to  $w_{i,t} - w_{i,t-}$ , where  $w_{i,t}$  is the new weight for fund  $i$  using time  $t$  information.

<sup>15</sup> The net returns of the long-short strategy are computed as the difference in the returns of the best (decile 10) and worst (decile 1) performing portfolios minus the sum of the transaction costs associated with both portfolios.
